Abstract

- AIM: To evaluate the short-term effect of the fixed combination of brinzolamide-timolol on the ocular surface in glaucoma patients.
- METHODS: This is a prospective study of 23 eyes of 23 patients with newly diagnosed glaucoma. Schirmer I test, tear break-up time (BUT) measurement, conjunctival impression cytology and central corneal thickness (CCT) measurements were performed in one of the eyes of each patient before and 4 weeks after brinzolamide-timolol fixed combination therapy. All patients were asked to answer the OSDI questionnaire form about the ocular surface symptoms at baseline and at 1 week and 4 weeks follow-up visits.
- RESULTS: After brinzolamide-timolol fixed combination therapy, Schirmer I, BUT and CCT values decreased but the only statistically significant decrease was seen in BUT test (P=0.03). OSDI scores increased during the follow-up but this increase was not statistically significant (P=0.22, P=0.42 respectively). Impression cytology findings ranged from 0.78±0.42 to 0.95±0.36 according to the Nelson classification. There was no statistically significant difference between baseline and 4 weeks follow up in impression cytology grades (P=0.15).
- CONCLUSION: The results of our study indicate that short-term use of brinzolamide-timolol fixed combination therapy does not have a profound effect on ocular surface except BUT values.
- KEYWORDS: fixed combination antiglaucoma drug; ocular surface; impression cytology

INTRODUCTION

Glaucoma is a leading cause of irreversible blindness throughout the world. Worldwide it has become the second most common cause of bilateral blindness [³]. At the present time, reduction of intraocular pressure (IOP) is the only proven effective therapy for reducing the risk of development or progression of glaucoma [²]. As in other disciplines of medicine, the decision on selection of hypotensive agent must be based on patient's findings. Also potential ocular and systemic side effects of the treatment with the patient's overall health and life expectancy must be taken into account. Adverse effects of topical hypotensive agents may have undesirable effect on ocular surface. In many studies ocular surface changes with anti-glaucomatous drugs have been investigated [³-⁵]. In addition, in many studies it has been demonstrated that these changes were identified as a risk factor for failure of trabeculectomy [⁶,⁷]. Although sometimes single ocular hypotensive agent is adequate, fixed combinations of topical hypotensive agents are frequently indicated to achieve more IOP reduction [⁹]. Besides the advantages of more IOP reduction, patient compliance to a one bottle instead of two and elimination of the washout effect are the other benefits of fixed combinations [⁹]. Also in a recent study Cho et al [⁹] showed that fixed combination antiglaucoma drugs can reduce the adverse ocular surface changes instead of two concomitant drugs in an experimental animal study. The authors explained the reduction in side effects were due to the small concentration of preservatives in the fixed combination.

A fixed combination of brinzolamide and timolol has recently been developed. Brinzolamide is a topical carbonic anhydrase inhibitor, reduces IOP by decreasing aqueous humour secretion [¹⁰]. Timolol is a β adrenergic blocker and reduces IOP by decreasing the aqueous humour formation [¹¹]
In recent studies brinzolamide 1% and timolol 0.5% fixed combination was found to be well tolerated with less ocular discomfort [13,14]. The purpose of this study was to evaluate the short-term effect of the fixed combination of brinzolamide-timolol on the ocular surface in glaucoma patients. We both evaluated the subjective symptoms [1] a questionnaire form (Ocular Surface Disease Index) and objective findings by Schirmer's test [1], impression cytology and tear break-up time (BUT) test.

SUBJECTS AND METHODS

Subjects Patients were eligible for participation if they met the following inclusion criteria: 18 years of age or older with open angle glaucoma without any medication previously and had not used any other topical medication for the last 1 month. Patients were required to have an IOP 21mmHg or more in at least 1 eye on 2 eligibility visits without any hypotensive agent.

Exclusion criteria were including known hypersensitivity to any component of the brinzolamide-timolol fixed combination, use of topical artificial tear preparations, any history or evidence of ocular surface disorders, any previous ocular surgery or laser treatment, a history of ocular infection or inflammation within the previous 3 months. Patients with any systemic disease or ocular disease that can affect ocular surface and also female patients with pregnancy and lactation were excluded.

Twenty five patients were enrolled; however, 23 patients completed the study. Two patients were excluded because of their hypersensitivity to the medication that they did not know before the treatment. Only one eye of each patient was involved randomly. Patients were instructed to use the drop twice daily at the same time of the day (around 9:00 AM and 9:00 PM). All patients were examined at baseline and at 1 week and 4 weeks after the medication beginning at the same time of the day.

This was a prospective, single-masked, single center clinical study. The study was reviewed and approved by institutional ethics committee and was conducted with the Declaration of Helsinki. All participating patients provided written informed consent.

Methods

Procedures Each patient underwent a full ophthalmic examination, including best-corrected visual acuity, IOP measurement with a Goldmann applanation tonometry, slit-lamp biomicroscopy, gonioscopy, stereoscopic fundus evaluation on the slit lamp using a 90 diopter lens, the Humphrey Field Analyzer (HFA) (Humphrey-Zeiss systems, Dublin, CA) Swedish Interactive Threshold Algorithm (SITA) 30-2 test. All patients were asked to answer the OSDI questionnaire form about the ocular surface symptoms at baseline and at 1 week and 4 weeks follow-up visits. Measurements were performed for all patients at baseline and at 4 weeks, including biomicroscopic evaluation, Schirmer's 1 test, BUT, central corneal thickness (CCT) and impression cytology after treatment. Ophthalmic examination and glaucoma diagnosis were performed by the same physician (Dr. PF). A masked physician performed the BUT. Two masked pathologists examined the impression cytology specimens.

Subjective Test

Ocular surface disease index In this study we used the Ocular Surface Disease Index (OSDI) to provide a rapid assessment of Ocular Surface Disease. The 12-item questionnaires in OSDI included ocular complaints and impact on the patient's life within last week. Five levels of symptom were presented and these 5 levels of score ranged from 0 (none of the time) to 4 (all of the time). The OSDI overall score ranged from 0 to 100 which 100 representing presence of a worse OSD and 0 representing absence of a problem. The total OSDI score was calculated as described previously [15] as follows:

\[
\text{OSDI score} = \frac{\text{sum of scores for all questions answered} \times 25}{\text{total number of questions answered}}
\]

A score of 12 or greater was considered as marker of OSD [16].

Objective Test

Tear function determination test

Schirmer 1 test: Schirmer 1 test with topical anesthesia was performed using Schirmer's paper strip placed in the lateral lower conjunctival sac. The paper strip was removed after 5 minutes and the length of the moistened area was recorded.

Break-up time test: To measure tear break up time (BUT), a drop of sodium fluorescein dye was instilled in the lower conjunctival sac. The tear film was observed under cobalt blue filtered light. The average interval between the last complete blink and the appearance of first dry spot on the precorneal film was calculated. Mean values of the three repeated measurements were obtained.

Impression cytology After instillation of a drop of proparacaine 0.5 %, a 4mm x 5mm Whatman nitrocellulose filter paper strip was applied to the inferior bulbar conjunctiva without any pressure. The paper peeled off with a forceps after 5 seconds and immediately transferred into a 95% ethanol. The specimens were stained with both Papanicolau's modification of Gill's technique and periodic acid-Schiff. The examination was performed according to the Nelson's method [17] under a light microscope. Two observers, similarly blinded, examined the specimens.

Grading system

Grade 0: The epithelial cells are small and round with eosinophilic-staining cytoplasm. The nucleuses are large, basophilic, and
nucleo-cytoplasmic ratio of 1/2. The goblet cells with an intensely PAS-positive cytoplasm are abundant, plump, and oval.

Grade 1:
In Grade 1 the epithelial cells are slightly larger and more polygonal and have eosinophilic-staining cytoplasm. The nucleo-cytoplasmic ratio is 1/3. The goblet cells are decreased in number however; they still maintain their plump oval shape, with an intensely PAS-positive cytoplasm.

Grade 2:
The epithelial cells are larger and polygonal, occasionally multinucleated with variably staining cytoplasm. The goblet cells are markedly decreased in number and are smaller, less intensely PAS-positive with poorly defined cellular borders.

Grade 3:
The epithelial cells are large and polygonal with basophilic-staining cytoplasm. The nuclei are small, pycnotic, and completely absent from many cells. The nucleo-cytoplasmic ratio is larger than 1/6. Goblet cells are completely absent.

Central corneal thickness measurement

Central corneal thickness (CCT) measurements were obtained using Pentacam-Scheimpflug imaging system. The system is based on a 180 degree rotating Scheimpflug camera that takes 12 to 50 single captures. The measurements were repeated 3 times and mean values were obtained. The Pentacam measurements were not affected by corneal deformation from Schirmer 1 and BUT, since they were performed first.

Statistical Analysis

For statistical analysis SPSS v.15. (SPSS Inc., Chicago, IL, USA) was used. Schirmer 1 test, BUT, impression cytology grades, CCT values and OSDI scores at baseline and follow up visits were compared using Wilcoxon test. Results are presented as mean±SD. A P-value less than 0.05 was accepted as being statistically significant.

RESULTS

Twenty-three patients with open angle glaucoma 14 women (60.8 %), 9 men (39.2 %) aged 51.5 years (range 20-79 years) were included in the study. Schirmer 1 test, BUT, CCT values for pre-treatment and post-treatment were shown in Table 1. OSDI scores at baseline and at 1 week and 4 weeks visits were shown in Figure 1.

After brinzolamide-timolol fixed combination therapy, Schirmer 1, BUT and CCT values decreased but the only statistically significant decrease was seen in BUT test (P=0.03). OSDI scores increased during the follow up but this increase was not statistically significant (P=0.22, P=0.42 respectively). Impression cytology findings ranged from (0.78±0.42) to (0.95±0.36) according to the Nelson classification. There was no statistically significant difference between baseline and 4 weeks follow up impression cytology grades (P=0.15).

DISCUSSION

In this study we investigated the effect of brinzolamide-timolol fixed combination therapy on ocular surface. We found no statistically significant difference in OSDI, Schirmer 1 test, CCT, impression cytology values between pre- and post-treatment. Although there was statistically significant difference between baseline and 4 weeks in BUT values.

Glaucoma is a chronic progressive disease and permanency of the treatment is required for a stable IOP reduction and visual field protection. Poor adherence to treatment is a serious problem for glaucoma patients. Most studies of adherence and persistence with glaucoma medications found that most of the patients discontinued the treatment within the 6 months [18,20]. In most of the glaucoma patients symptoms are mild or absent and treatment is prophylactic so using eye drops sometimes can be seen meaningless by the patients. Poor adherence is generally related to many factors, and one of them is side effects of the eye drops [21]. Therefore, the effects of the drugs on tear film, conjunctiva and cornea are important issues to be examined. These side effects may occur depending on the active agent or preservative [22]. Brinzolamide-timolol fixed combination contains benzalkonium chloride (BAK). Several studies confirmed the toxic effect of BAK against the ocular surface [23,24]. However, there is not any study comparing the effects of BAK preserved to BAK free brinzolamide-timolol fixed combination on ocular surface.

The goal of this study was to evaluate the effect of brinzolamide-timolol fixed combination on ocular surface. So we use both objective and subjective methods to strengthen the study. OSDI was used for subjective...
measurement. OSDI scores were not statistically changed during the follow up from baseline. Although at the baseline visit with the objective markers of ocular surface disease (OSD) such as Schirmer 1 test and BUT, OSD was not recognized in any patients. The mean OSDI score at baseline was showing OSD with a score of (19.7±10.8). Similarly to our results, previous studies demonstrated a poor correlation between patient symptoms and objective tests. Possible explanations can be inconsistent clinical signs, the heterogeneity of dry eye disease, and the instability of the tear film in elderly patients.

We did not observe any significant difference in Schirmer's I and impression cytology grades between baselines and follow up visits. BUT was the only parameter of statistically significant decrease. The time required for onset of the metaplasia has not been demonstrated before, however in a long-term study it has been suggested that it was less than three months. Whereas another study suggested that the time required for onset of the metaplasia is less than one month.

The decrease in conjunctival goblet cell density was accepted as the most important parameter in assessing the OSD, which results in outside the normal Schirmer and BUT. In a multicenter study with 72 patients switched from dorzolamide-timolol to brinzolamide-timolol combination Rossi et al. found significantly improvement in Schirmer and BUT. The improvement in Schirmer and BUT results in patients preference which may improve adherence.

Blurred vision is a problem with brinzolamide-timolol fixed combination because of its suspension form. Despite this problem in a study that was made by Mundorf et al. 79.2% of patients preferred brinzolamide-timolol fixed combination. In a recent multicenter study with 14025 patients Lanzl and Raber demonstrated that 75.9% of the patients preferred brinzolamide-timolol fixed combination over the previous treatment.

Carbonic anhydrase 2 is also expressed in corneal endothelium. So, prescription of a carbonic anhydrase inhibitor (CAI) needs a careful evaluation of corneal endothelial function. The effect of brinzolamide on corneal endothelial cell function has been evaluated by March et al. They observed no meaningful decrease in endothelial cell density or in corneal thickness between treatment groups over the 18 months. CCT was reported as an indicator of corneal endothelial pump and barrier functions. We evaluated the CCT at baseline and 4 weeks visit to assess the effect of brinzolamide-timolol fixed combination on corneal endothelial cell function. We did not find any statistically significant difference in CCT.

In conclusion, we investigated the short-term effect of brinzolamide-timolol fixed combination on corneal surface using objective and subjective methods. We did not observe any significant difference on the parameters except BUT. Long-term studies with a greater number of patients are required to see the effect of brinzolamide-timolol fixed combination on ocular surface.
