Abstract

- **AIM:** To investigate the effect of internal limiting membrane transplantation and autologous blood on treating refractory giant macular hole.
- **METHODS:** Thirty-seven eyes with giant macular hole of the smallest hole diameter >700 μm, the maximum diameter of the substrate >1000 μm and hole formation factor <0.6 underwent surgical treatment. The patients were randomly divided into two groups. Nineteen eyes with surgical flip of the internal limiting membrane in group A, 18 eyes with internal limiting membrane transplantation in group B who underwent the tamponade of internal limiting membrane into the hole, autologous plasma was used to seal the hole. The patients were followed up for 3mo, optical coherence tomography and best corrected visual acuity (BCVA) were recorded before and after operation, and the results were statistically analyzed.
- **RESULTS:** At 3mo after operation, BCVA of the two groups was significantly improved compared with that before operation ($t_A=4.192$, $t_B=4.374$, $P<0.05$). But there was no significant difference in visual acuity between the two groups ($\chi^2=0.128, P>0.05$). At 3mo after operation, the closure rate of group A was 68.4%, and 100% in group B. ($\chi^2=5.628, P<0.05$). The defect diameter of inner segment/outer segment at 3mo after the operation was significantly lower than that before operation ($t_A=12.287$, $t_B=15.481$, $P<0.05$), and the difference was statistically significant ($t=2.552, P<0.05$).
- **CONCLUSION:** Internal limiting membrane transplantation combined with autologous whole blood can improve the postoperative closure rate of the refractory large aperture, and can effectively improve the postoperative visual acuity.

INTRODUCTION

Macular hole (MH) is a retinal neuroepithelial layer of macular tissue defect, the incidence rate is about 0.6%-0.7%, MH can occur in all ages, is a serious damage to eyesight. There may be many causes of MH, such as ocular trauma, high myopia, endophthalmitis, laser burns and cystoid macular edema, some of which are unknown, such as idiopathic macular hole (IMH). IMH is more common in middle-aged and older women, most of them are monocular disease, the incidence of binocular vision is about 12%, The prevalence rate was 3.3% in people over 55 years old[1]. The progressive MH need to be solved by timely vitrectomy surgery, in order to avoid secondary retinal detachment, resulting in further loss of vision. At present, vitrectomy combined with internal limiting membrane (ILM) peeling has improved the closure rate of IMH as high as 90%[2-3], but for the larger diameter of refractory MH underwent vitrectomy combined with ILM peeling, postoperative closed rate is low[4]. The reasons for this are not clear, and it maybe related to decreased retinal pigment epithelial (RPE) function. In order to improve closure rate of such IMH, we creatively use ILM transplantation combined with autologous whole blood treatment for which minimum diameter is >700 μm, the maximum base diameter is 1000 μm, hole formation factor (HFF) is >0.6, and observe the clinical effect after operation. To the end, we prospectively studied 37 patients with IMH of the minimum diameter of >700 μm, the maximum base diameter of 1000 μm, HFF>0.6 in the Department of Ophthalmology, No.474 Hospital of the PLA, from October 2016 to February 2017.

**SUBJECTS AND METHODS**

**Subjects** This study collected 37 eyes of 37 cases with the minimum IMH diameter of >700 μm, the maximum base
diameter of 1000 μm, HFF>0.6 in the hospital center in October 2016 to February 2017. There were 3 males and 34 females, aged 56-72 (mean 62.80±9.35) years old, and associated with decreased vision and metamorphopsia. All the patients were randomly divided into two groups: group A (19 eyes) and group B (18 eyes). Exclusion criteria: 1) with retinal detachment; 2) a history of vitreous body and retinal surgery; 3) with high myopia, vitreous body and retinal disease, cataract, glaucoma, ocular trauma and other eye diseases; 4) surgical contraindications to systemic and ocular vitreous body. The study was approved by the hospital ethics committee and all participants signed informed consent.

Surgical Methods All operations were performed by the same surgeon who had extensive experience in vitreous surgery. In group A, all patients underwent conventional 23G vitrectomy through pars plana corporis ciliaris, and the hole of the macular area was covered with stripped ILM after indocyanine green staining. In group B, all patients underwent conventional 23G vitrectomy through pars plana corporis ciliaris, and annular detachment of ILM in macular after indocyanine green staining. The valve with the size of the hole in the central part of the left side of the nasal side (like a tennis racket), and ILM staining. The valve with the size of the hole in the central part of the left side of the nasal side (like a tennis racket), and ILM staining. The valve with the size of the hole in the central part of the left side of the nasal side (like a tennis racket), and ILM staining. The valve with the size of the hole in the central part of the left side of the nasal side (like a tennis racket), and ILM staining. The valve with the size of the hole in the central part of the left side of the nasal side (like a tennis racket), and ILM staining. The valve with the size of the hole in the central part of the left side of the nasal side (like a tennis racket), and ILM staining. The valve with the size of the hole in the central part of the left side of the nasal side (like a tennis racket), and ILM staining.

Observation Index Best corrected visual acuity (BCVA), fracture closure, inner segment/outer segment (IS/OS) defect diameter were recorded at preoperative and 3mo after operation. Optical coherence tomography (OCT) was used to evaluate the MH closure: 1) complete closure: the nerve epithelium completely covers the naked pigment epithelium, and the neuroepithelial tissue can be seen in the macula, but can be partially replaced by scar; 2) part of the closure: nerve epithelium and pigment epithelium are clothing in the edge of the fissure, retinal subside in the hole periphery, the center of the macula is completely replaced by scar tissue; 3) unclosure: MH edge detachment.

Statistical Analysis Statistical software SPSS18.0 was used to analyze the data, paired t-test was used to compare BCVA and the diameter of IS/OS before and after operation, application of chi square test to the closure of MH, the test level was 0.05, which was statistically significant at P<0.05.

RESULTS Vision There were 16 cases in group A with higher BCVA than preoperative, and the improvement rate was 84.2%. In group B, 16 cases were improved, the improvement rate was 88.9%. BCVA was significantly improved compared with preoperative in two groups 3mo after operation (tA=4.192, tB=4.374, P<0.05). But there was no significant difference in visual acuity between the two groups (t=0.128, P>0.05).

Macular Hole Closure The macular area was observed 1d after operation through the gas on, procumbent macular area can be showed in group A; in group B, the whole blood was found in the macular 1d after operation. Blood absorbed gradually after 1wk and the MH could be observed by gas after 10d. At 1mo after operation, the OCT scan could clearly observe transplanted ILM tissue in MH. At 3mo after operation, there were 5 cases in group A appear neuroepithelial layer cavity defect in OCT. It is suggested that the MH is not complete closure (Figure 2). In 1 case, the MH was not closed and visible superior ILM flap in OCT, MH closure rate was 68.4%. In the group B, the epithelium of the nerve or ILM was completely covered the exposed pigment epithelium and MH closure rate was 100% (Figure 3). The difference between the two groups was statistically significant (X²=5.628, P<0.05).

Optical Coherence Tomography The defect diameter of IS/OS 3mo after the operation was significantly lower than that before operation (tA=12.287, tB=15.481, P<0.05), and the difference was statistically significant (t=2.552, P<0.05) between the two groups.

Complications The posterior limiting membrane of vitreum and ILM were successfully identified with the assistance of triamcinolone acetonide and indocyanine green. None of the patients had iatrogenic hole formation. A patient had a glaucoma attack on the side of the surgery eye after the follow-up, and intraocular pressure (IOP) decreased to normal after drug treatment.

DISCUSSION IMH is a primary eye disorder that threatens the vision of middle-aged patients. Timely treatment of IMH helps prevent the development of secondary retinal detachment. The aetiology and pathogenesis of IMH are not well understood. IMH may be linked to posterior vitreous traction, in which the tractional force is generated in the tangential or vertical direction during the vitreous liquefaction process.
Currently, many surgical methods are available for the treatment of IMH, but there is controversy about which method is the best. A large number of literatures have confirmed that vitrectomy combined with ILM peeling can effectively improve the postoperative closure rate of MH\[7-10\]. As shown in some reports, completely removing the posterior vitreous cortex and peeling ILM promotes the closure of MHs because the procedure stimulates the proliferation of RPE cells, which results in the formation of a fibrotic or scarring lesion that covers and closes the holes\[11\]. Many factors can affect the postoperative closure of MHs and the visual prognosis, including the minimum diameter of the hole, maximum diameter of the basal hole, height of the hole, and HFF. In particular, Woon et al\[12\] suggest that the minimum hole diameter and maximum basal hole diameter are the most important factors that affect postoperative MH closure and vision. Salter et al\[13\] suggest that postoperative therapeutic efficacy is best when an MH has a minimum diameter of <500 μm and a maximum basal diameter of <1000 μm. If an MH has a minimum diameter of >500 μm, its closure rate is lower after vitrectomy and ILM peeling, and the postoperative visual recovery is also worse. Further, the likelihood that a second surgery would be required significantly increasing, and the hole closure rate following the second surgery is much lower than the first surgery\[14\]. Refractory MHs with an HFF value of <0.6 have only a 67% closure rate after vitrectomy and ILM peeling\[14\]. To enhance postoperative closure rate of refractory MHs and achieve better surgical outcomes, researchers worldwide have performed a variety of modified surgeries, including ILM peeling, partial ILM preservation, and inverted ILM insertion\[15\]. An IMH with a maximum diameter of <400 μm has a postoperative closure rate of more than 90% after vitrectomy and ILM peeling\[16\]. However, bigger holes have lower closure rates, with as many as 44% of MHs failing to be closed after the first surgery and requiring a second surgery\[17-18\]. Gass et al\[19\] modified MH surgery and applied an inverted ILM flap technique, achieving...
with a closure rate of 68.4%. This phenomenon was likely a
result of poor prone position compliance and decreased RPE
function. The RPEs at the holes in group B were all covered
by the RNL or ILM, with a 100% hole closure rate (Figure 3).
OCT scanning suggested that the defect diameter of the
photoreceptor IS/OS junction was significantly smaller than
that before surgery ($t_a=12.287$, $t_d=15.481$, $P<0.05$). During
the postoperative follow-up, one patient had a glaucoma attack
in the contralateral eye, but IOP dropped to normal after drug
therapy. IOP of the operated eye was normal throughout the
follow-up, therefore, this patient likely had predisposition
for glaucoma. The results of this study imply that ILM
transplantation with autologous whole blood application
could promote postoperative visual recovery in patients
with refractory MHs. Covering the hole with autologous whole
blood and filling the vitreous chamber with inert gas were both
beneficial to fixing ILM transplanted in the MH. During this
surgery, great care should be taken during the process of fluid-
gas exchange to prevent sucking out the introduced whole
blood and the transplanted ILM.

The findings of this study indicate that vitrectomy with
both ILM transplantation and autologous whole blood may
significantly increase postoperative hole closure rate in
patients with refractory MHs (minimum diameter >700 µm,
maximum basal diameter >1000 µm, and HFF <0.6) and
may dramatically enhance the visual functions of patients,
rendering this surgical approach safe and effective. Moreover,
we demonstrated that intraoperative blood collection is easily
performed and the probability contamination is extremely
low. However, further exploration is necessary to determine
whether this surgical approach is applicable to other forms of
refractory MHs and if indocyanine green-stained ILM would
result in adverse side effects in the retina.
